3D motion tracking is a critical task in many computer vision applications. Unsupervised markerless 3D motion tracking systems determine the most relevant object in the screen and then track it by continuously estimating its projection features (center and area) from the edge image and a point inside the relevant object projection (namely, inner point), until the tracking fails. Existing reliable object projection feature estimation techniques are based on ray-casting or grid-filling from the inner point. These techniques assume the edge image to be accurate. However, in real case scenarios, edge miscalculations may arise from low contrast between the target object and its surroundings or motion blur caused by low frame rates or fast moving target objects. In this paper, we propose a barrier extension to casting-based techniques that mitigates the effect of edge miscalculations.

I. INTRODUCTION

Optical motion tracking, simply called motion tracking in this paper, means continuously locating a moving object in a video sequence. 2D tracking aims at following the image projection of objects that move within a 3D space. 3D tracking aims at estimating all six degrees of freedom (DOFs) movements of an object relative to the camera: the three position DOFs and the three orientation DOFs [11].

A 3D motion tracking technique that only estimates the three position DOFs (namely moving up and down, moving left and right, and moving forward and backward) is enough to provide a three-dimensional cursor-like input device driver [12, 13].

Such an input device could be used as a standard 2D mouse-like pointing device that considers depth changes to cause mouse-like clicks. It also settles the bases for the development of virtual device drivers (i.e. software implemented device drivers, or not hardware device drivers) that consider three-dimensional position coordinates.

Real-time 3D motion tracking techniques have direct applications in several huge niche market areas [16]: the surveillance industry, which benefits from motion detection and tracking [3, 8, 10]; the leisure industry, which benefits from novel human-computer interaction techniques [7, 15]; the medical and military industries, which benefit from perceptual interfaces [2], augmented reality [5], and object detection and tracking [1, 4, 6]; and the automotive industry, which benefits from driver assistance systems [9].

A 3D motion tracking system that only requires a single low-budget camera can be implemented in a wide spectrum of computers and smartphones that already have such a capture device installed.

There exist unsupervised markerless 3D motion tracking techniques [12–14] that need no training, calibration, nor knowledge on the target object, and only require a single low-budget camera and an evenly colored object

that is distinguishable from its surroundings.

These motion tracking techniques consist of a subsystem that determines the most relevant object in the screen, and a subsystem that performs the tracking by continuously estimating the target object projection features (center and area) from the edge image and a point inner to the object projection.

Existing object projection feature estimation techniques perform ray-casting [12, 13] or grid-filling [14] from the inner point and estimate the center as the average of the ray hit location positions and the area as the coverage of the rays.

These techniques assume the edge image to be accurate. However, in real case scenarios, edge miscalculations may arise from low contrast between the target object and its surroundings or motion blur caused by low frame rates or fast moving target objects.

In this paper, we propose a barrier extension to casting-based techniques that mitigates the effect of edge miscalculations.

Section II covers the definition of the object projection feature estimation problem and the existing techniques for solving it. Section III describes our barrier extension to casting-based techniques. Finally, Section 6 summarizes the obtained conclusions and discloses the future work that derives from our research.

II. BACKGROUND

Unsupervised markerless 3D motion tracking techniques requires estimating the centroid and the area of the projection of a target object given an edge image and a point inside the object projection (namely, inner point) [12, 13]. The inner point also has to be updated to increase the probabilities of it being inside the object projection in the next frame. We call this the object projection feature estimation problem.

Figure 1 depicts examples of a convex object projec-

tion feature estimation problem and a non-convex object projection feature estimation problem.

Figure 1 The object projection feature estimation problem consists in, given an edge image and a point inside the object projection (namely, inner point), estimating the object projection centroid, the object projection area, and updating the inner point in order to increase the probabilities of it being inside the object projection in the next frame. Example of a convex object projection feature estimation problem (sphere projection) and to a non-convex object projection feature estimation problem (hand projection).

It should be noted that the inner point can be found enclosed in a small isolated area (e.g. a finger, when the target object is a hand).

It also should be noted that, due to the object movement between frames, it is possible for the current inner point to be relocated at a position that will be outside the object projection in the next frame.

Each one of the following subsections describes an approach for solving the object projection feature estimation problem.

A. Feature Estimation Based on n -Ray-Casting

Using this technique, n rays are casted from the inner point position in different directions to hit an edge in the edge image [12, 13].

The new centroid position is estimated to be the average of the ray hit location positions.

In order to estimate the inner point, it is displaced towards the new centroid until it reaches it or an edge. Then, rays are casted from the inner point and it is relocated at the average of the ray hit location positions, in order to center it in the projection area it is located, which reduces the probability of it being outside the object projection in the next frame.

The area is estimated to be the sum of the lengths of the casted rays.

Figure 2 illustrates 32-ray-casting being applied to a convex object projection and to a non-convex object projection.

Figure 2 32-ray-casting being applied to the estimation of the features of a convex object projection (sphere projection) and to a non-convex object projection (hand projection).

The main drawback of this technique is that the estimations may not be accurate when it is applied to non-convex object projections (e.g. a hand projection). In that case, the ray hit locations might be representative of just a fragment of the projection, in particular when the inner point is in a small isolated area of the object projection. The centroid and the area might be inaccurately estimated, and the estimations may greatly vary depending on the position of the inner point relative to the object projection and on the ray orientations.

The likeliness of edge miscalculations (i.e. the edges not being calculated correctly) to have high impact in the projection area and centroid estimations is inversely proportional to n .

B. Feature Estimation Based on Iterative n -Ray-Casting

This technique is an iterative extension to n -ray-casting [12, 13].

Using this technique, n rays are casted from the inner point position in different directions to hit an edge in the edge image.

The new centroid position is estimated to be the average of the last iteration ray hit location positions.

The inner point is displaced towards the new centroid until it reaches it or an edge.

The process is repeated until the centroid and inner point adjustment is negligible or up to a maximum number of iterations.

Then, rays are casted from the inner point and it is relocated at the average of the ray hit location positions,

in order to center it in the projection area it is located, which reduces the probability of it being outside the object projection in the next frame.

The area is estimated to be the sum of the rays casted during the last iteration.

Figure 3 illustrates two steps of iterative 32-ray-casting being applied to a convex object projection and to a non-convex object projection.

Figure 3 Two steps of iterative 32-ray-casting being applied to the estimation of the features of a convex object projection (sphere projection) and to a non-convex object projection (hand projection). Images on the left show the first iteration. Images on the right show the second iteration.

It should be noted that iterative n -ray-casting can relocate the inner point into wider areas and therefore produce better estimations of the object projection centroid and area. Indeed, it can be observed that it produces better results than n -ray-casting when the target object is non-convex and the inner point is in a small isolated area of the target object projection.

Although this technique being iterative makes the centroid tend to be relocated into wider areas, the estimations are still not accurate when the technique is applied to non-convex object projections, as the ray hit locations might be representative of just a fragment of the object projection.

It should be noted that the centroid is not guaranteed to converge, and the estimations may greatly vary depending on the position of the inner point relative to the object projection, on the ray orientations, and on the maximum number of iterations.

The likeliness of edge miscalculations to have high impact in the projection area and centroid estimations is inversely proportional to n .

C. Feature Estimation Based on Iterative n^y -Ray-Casting

This technique is an extension to iterative n -ray-casting [12, 13].

Using this technique, n rays are casted from the inner point position in different directions to hit an edge in the edge image.

Then, n rays are casted from each of the last iteration ray hit location position. This re-casting process is repeated y times for a total of n^y rays being casted in the latest iteration.

The new centroid position is estimated to be the average of the last iteration ray hit location positions.

The inner point is displaced towards the new centroid until it reaches it or an edge.

Then, rays are casted from the inner point and it is relocated at the average of the ray hit location positions, in order to center it in the projection area it is located, which reduces the probability of it being outside the object projection in the next frame.

The process is repeated until the centroid and inner point adjustment is negligible or up to a maximum number of iterations.

The area is estimated to be the sum of the rays casted during the last iteration.

Figure 4 illustrates 16²-ray-casting being applied to a convex object projection and to a non-convex object projection.

Figure 4 Two steps of iterative 16²-ray-casting being applied to the estimation of the features of a convex object projection (sphere projection) and to a non-convex object projection (hand projection). Images on the left show the first iteration. Images on the right show the second iteration.

It should be noted that the inner point is relocated into wider areas in non-convex object projections very slowly, due to isolated areas near the current inner point having a higher ray-density than wider areas, rendering the later less relevant for the estimation of the projection centroid

and area. On the other hand, iterative n^y -ray-casting covers the projection better than iterative n -ray-casting, and therefore outperforms it.

It should be noted that this technique, as n -ray-casting, does not guarantee the centroid to converge, and results may still greatly vary depending on the position of the inner point relative to the object projection, on the ray orientations, and on the maximum number of iterations.

The likeliness of edge miscalculations to have high impact in the projection area and centroid estimations is inversely proportional n^y . It should be noted that edge miscalculations near the inner point may produce very inaccurate results.

D. Feature Estimation Based on Iterative n^y -Ray-Casting with m -Rasterization

This technique is an extension to iterative n^y -ray-casting [12, 13] that solves its problems.

Using this technique, n rays are casted from the inner point position in different directions to hit an edge in the edge image.

Then, n rays are casted from each of the last iteration ray hit location position. This re-casting process is repeated y times for a total of n^y rays being casted in the latest iteration.

Now, a rasterization process takes place. Every $m \times m$ block that was run through by any of the rays is selected.

The new centroid position is estimated to be the average of the selected block positions.

The inner point is displaced towards the new centroid until it reaches it or an edge.

Then, rays are casted from the inner point and it is relocated at the average of the ray hit location positions, in order to center it in the projection area it is located, which reduces the probability of it being outside the object projection in the next frame.

The process is repeated until the centroid and inner point adjustment is negligible or up to a maximum number of iterations. It should be noted that, as blocks always represent areas inside the object projection, no blocks are unselected between iterations.

The area is estimated to be the sum of the selected block areas.

Figure 5 illustrates 16^2 -ray-casting with 8-rasterization being applied to a convex object projection and to a non-convex object projection.

It should be noted that the inner point moves to wider areas in non-convex object projections quicker than when applying iterative n^y -ray-casting, due to high-ray-density areas being given the same relevance as low-ray-density areas. Less iterations are necessary for the estimations to be accurate, therefore processing times are lower than those of iterative n^y -ray-casting without rasterization, although they may still be prohibitive for certain applications. It also should be noted that when m is too high,

the projection centroid and area estimations will be imprecise due to low resolution in block selection; when m is too low, the technique behaves as iterative 16^2 -ray-casting without rasterization, which makes the inner point to be slowly displaced.

Figure 5 Two steps of iterative 16^2 -ray-casting with 8-rasterization being applied to the estimation of the features of a convex object projection (sphere projection) and to a non-convex object projection (hand projection). Images on the left show the first iteration. Images on the right show the second iteration.

As the selected blocks are kept between iterations, the inner point and the centroid are guaranteed to converge. Although results may vary depending on the position of the inner point relative to the object projection, on the ray orientations, and on the maximum number of iterations, they will be similar for convex object projections and non-convex object projections with not too large isolated areas.

The likeliness of edge miscalculations to have high impact in the projection area and centroid estimations is inversely proportional to $n^y \cdot i$, being i the number of performed iterations, as the final estimations depends on rays casted during any iteration.

Filling-based techniques consist in locating every piece of the object projection until reaching the edges, and therefore fit the object projection better than ray-casting-based techniques. Depending on the resolution and the parameters, filling-based techniques may also require a lower processing time than some of the more complex iterative ray-casting-based techniques. It should be noted that, when using filling-based techniques, the feature estimations calculated from different inner points located in different parts of the same object will be the same.

E. Feature Estimation Based on Pixel-Filling

This technique is an approach to the object projection feature estimation problem that requires a lower processing time than ray-casting-based techniques.

Using this technique, the object projection is covered by filling it up to the edges.

A pixel queue is initialized with the inner point position pixel. While the queue contains pixels, a pixel is extracted from the queue. If the pixel is an edge in the edge image, it is ignored. If the pixel is not an edge, it is marked as part of the object projection and all the pixels next to it that have not been marked are added to the queue.

The new centroid position is estimated to be the average of the marked pixel positions.

The inner point is displaced towards the new centroid until it reaches it or an edge. Then, rays are casted from the inner point and it is relocated at the average of the ray hit locations, in order to center it in the projection area it is located, which reduces tracking errors.

The area is estimated to be the number of the marked pixels.

Figure 6 illustrates pixel-filling being applied to a convex and a non-convex object projection.

Figure 6 Pixel-filling being applied to the estimation of the features of a convex object projection (sphere projection) and to a non-convex object projection (hand projection).

It should be noted that this technique does not need to be iteratively applied, and the obtained results are the same independently of the inner point position.

However, this technique presents a major drawback that renders it unusable: edge miscalculations have high impact in the projection area and centroid estimations, as a single-pixel edge miscalculation would allow the filling to expand out of the actual object projection.

F. Feature Estimation Based on m -Grid-Casting

This technique is an approach to the object projection feature estimation problem that solves the aforementioned pixel-filling-based technique problem.

Using this technique, a grid consisting of $m \times m$ cells is casted centered in the inner point position and expanded until it reaches the edges.

A pixel queue is initialized with the inner point position pixel. While the queue contains pixels, a pixel is extracted from the queue. If the pixel is an edge in the edge image, it is ignored. If the pixel is not an edge, it is marked as part of the object projection and all the pixels next to it that would be in the grid and that have not been marked are added to the queue.

The new centroid position is estimated to be the average of the grid pixel positions.

The inner point is displaced towards the new centroid until it reaches it or an edge. Then, rays are casted from the inner point and it is relocated at the average of the ray hit locations, in order to center it in the projection area it is located, which reduces tracking errors.

The area is estimated to be the number of the grid pixel positions.

Figure 7 illustrates grid-casting being applied to a convex and a non-convex object projection.

Figure 7 8-grid-casting being applied to the estimation of the features of a convex object projection (sphere projection) and to a non-convex object projection (hand projection).

It should be noted that this approach solves all the problems of the aforementioned techniques: it is not as processing-time intensive as iterative n -ray-casting; it produces similar results independently of the inner point position; it allows the estimation of features of non-convex objects; it makes non-convex zones to be as relevant as convex-zones, as the grid pixel density is the same in the whole object projection; and the likeliness of edge miscalculations to have high impact in the pro-

jection area and centroid estimations is not as high as filling-based techniques’.

Also, as the grid size can be configured, the processing time requirements can be adjusted for low budget processor devices such as smartphones.

III. USING BARRIERS IN CASTING TECHNIQUES

The studied object projection feature estimation techniques are sensitive to edge miscalculations in different degrees. A single edge miscalculation (e.g. an edge pixel not marked as edge) may cause ray-casting, pixel-filling and grid-filling to spread outside of the object projection and significantly alter the feature estimations, causing failures in the motion tracking.

Each time a target pixel is visited in ray-casting- or grid-filling-based techniques, it is accessed from a source neighboring pixel. The vector determined by the source and target pixel positions provides context information that can be exploited to enhance the detection of edge collisions, thus allowing the enhancement of the existing object projection feature estimation techniques.

Existing techniques check if a pixel that is to be visited is an edge pixel in the edge image, in which case it is discarded. It should be noted that, in this case, a pixel-wide edge miscalculation is enough to cause very inaccurate results, as the casting can progress after the undetected edge and spread to other object projections, as seen in Figure 8

visited	visited	visited	edge		
visited			edge		
visited			edge		
visited			edge		
visited	visited	visited	edge miss		
visited			edge		

Figure 8 Even single edge miscalculations allow ray-casting, pixel-filling and grid-filling to spread outside of the object projection.

We propose the use of barriers in ray-casting- and grid-filling-based techniques to mitigate the impact of edge miscalculations in object projection feature estimation. When using barriers, a barrier perpendicular to the vector determined by the source and target pixel positions is computed. Instead of checking a single pixel in order to progress, the whole barrier of pixels is checked, and if any of the barrier pixels are edge pixels, the target pixel is discarded, as seen in Figure 9.

Since ray-casting and grid-filling techniques usually

visited	visited	visited	edge		
visited			edge		
visited			edge		
visited		→	edge		
visited	visited	→	edge miss		
visited		→	edge		

Figure 9 A simple barrier strategy avoids ray-casting, pixel-filling and grid-filling to spread outside of the object projection through edge miscalculations.

reach each zone of the object projection from different pixels (i.e. with different vectors), spurious edge pixels would cause different barriers to be considered, therefore they would not negatively affect the results.

The size of the barrier can be adjusted to any odd number. A minimal barrier of size 3 makes the techniques insensitive to edge miscalculations of up to 2 pixels wide. A barrier of size 5 makes the techniques insensitive to edge miscalculations of up to 4 pixels wide.

The implementation of barriers in existing techniques only increases the constant multiplicative factor of the algorithm, and it greatly improves the results of ray-casting and grid-filling object projection feature estimation techniques.

IV. CONCLUSIONS AND FUTURE WORK

In this paper, we have studied the object projection feature estimation problem in 3D motion tracking and we have studied the existing ray-casting-based and grid-casting-based techniques for solving it.

We have proposed the use of barriers during the casting, which makes the existing techniques less sensitive to edge miscalculations.

Our proposal allows the development of more accurate unsupervised markerless 3D motion tracking systems.

Also, as our proposal reduces the error on the feature estimations, and these errors could cause tracking errors, it allows the development of more robust unsupervised markerless 3D motion tracking systems.

We plan to keep reducing the impact of edge miscalculations in the feature estimations by using color-space information.
